Single atoms form a model system for understanding the limits of single-photon detection. Here, we develop a non-Markovian theory of single-photon absorption by a two-level atom to place limits on the absorption (transduction) time. We show the existence of a finite rise time in the probability of excitation of the atom during the absorption event which is infinitely fast in previous Markov theories. This rise time is governed by the bandwidth of the atom-field interaction spectrum and leads to a fundamental jitter in time stamping the absorption event. Our theoretical framework captures both the weak and strong atom-field coupling regimes and sheds light on the spectral matching between the interaction bandwidth and single-photon Fock state pulse spectrum. Our work opens questions whether such jitter in the absorption event can be observed in a multimode realistic single-photon detector. Finally, we also shed light on the fundamental differences between linear and nonlinear detector outputs for single-photon Fock-state vs coherent-state pulses.

I. INTRODUCTION

Recently, single-photon detectors with high efficiency (>90%) [1], low dark-count rate (<1 mHz) [2], and reduced timing jitter (<20 ps) [3] have raised substantial interest due to their widespread applications in quantum information processing [4,5], imaging, sensing and ranging, and astronomy. Single-photon detectors based on superconducting nanowires or semiconductor avalanche photodiodes [6] are threshold detectors fundamentally different from conventional coherent photoreceivers. They typically work by outputting a classical electrical signal that results from the amplification of a weak quantum signal generated within the detector after the transduction event (photon absorption).

While the classical response of the amplifier stage currently dominates the characteristics of the single-photon detector, it is important to note that the initial transduction process from photons to detector modes is fundamentally probabilistic in nature. As absorption mode volumes are decreased and amplifiers are improved, it is plausible that quantum limits of single-photon transduction to detector modes will eventually manifest itself. For example, currently the timing jitter of a single-photon detector is defined by using the deterministic output voltage signal where familiar concepts of rise time and fall time of classical electrical signals can be applied. However, rising edges and fall times can also be defined for quantum signals during the initial single-photon transduction event through the time-dependent excitation probability of detector modes in a statistical sense. Thus even an ideal single-photon detector will be noninstantaneous and the rise times and falling edges of the quantum signal will set fundamental limits on the timing jitter performance.

Glauber’s theory of quantum photodetection and related work only provide the average counting rate of an ideal detector, which is proportional to the first-order coherence of the electromagnetic field [7,8]. In this class of approaches, the interaction between light and the ideal detector is based on first-order perturbation theory similar to Fermi’s golden rule. The properties of the detector, which is only weakly coupled to the electromagnetic field, thus cannot be characterized beyond averaged absorption and emission times (e.g., Einstein’s $A$ and $B$ coefficients for an atom in thermal equilibrium [9]). Thus this approach cannot give any information on the rise time or fall time of the quantum or classical output signal of the detector.

In this paper, we study the single atom as a model system to understand limits of the initial transduction event within an ideal narrowband single-photon detector. Here, the output signal is the time-dependent excitation probability of the atom for an incident single-photon pulse. We utilize an exactly solvable nonperturbative model to show the behavior of rise times and fall times of the output signal from such an atomic photodetector. We show that a non-Markovian theory is essential to understand the fundamental limit of the absorption (transduction) event. We also study the atom-field interaction beyond the weak-coupling limit for various Fock state pulse envelopes and set limits on the rise times and fall times for atomic excitation probability. We expect these results to be a starting point for developing a complete theory for a multimode broadband single-photon detector beyond weak interactions.

We note that the absorption [10–13] and scattering [14–26] of a propagating single- or multiphoton pulse by a single atom have been extensively studied theoretically and also experimentally [26–30]. In particular, important recent work has shown the role of multimode quantum pulses and interactions with atoms [11,13,14]. However, in the case of ultrashort incident pulses, most previous theories are not directly applicable. This is due to the widely utilized Markov approximation which allows for instantaneous detector response times and...
thus cannot set limits to the single-photon transduction event [10–13]. Note that the field of non-Markovian dynamics has recently given rise to widespread interest in the field of open quantum systems. In particular, non-Markovian theories have been previously utilized for single atoms in a cavity for memory applications and scattering in one-dimensional (1D) waveguides [31] as well as 1D lattices [32]. However, the necessity of a non-Markovian theory to explore the timing jitter of the single-photon absorption event in an atom has not been realized. We also discuss in our work the strong-coupling regime of cavity QED which cannot be reached for a free-space atom interacting with a single-photon pulse. We also note that density-of-states engineering directly controls only the spontaneous emission, i.e., the fall time of the probability amplitude of the excited atom. Our focus in this paper is the fundamental limit in the absorption time or rise time in the excitation probability.

This paper is organized as follows: In Sec. II, the model and non-Markovian theory to describe single-photon transduction by a single atom is presented. The limits to the transduction time and the concept of quantum timing jitter are given in Sec. III. In Sec. IV, we study the role of the spectral match between the Fock state pulse and the atom-field interaction spectrum. In Sec. V, we study the fundamental difference between linear and nonlinear detector outputs for different types of quantum pulse. Finally, we collect our main conclusions in Sec. VI. The details of the wave function and spectral amplitude of a single-photon pulse are given in Appendix A and some detailed calculation about the excitation probability of the atom is presented in Appendix B.

II. NON-MARKOVIAN THEORY OF SINGLE-PHOTON ABSORPTION BY A SINGLE ATOM

In this section we define our model and provide the non-Markovian theory of photon transduction before applying it to explore timing jitter. We study the absorption of a single-photon Fock state (SPFS) pulse propagating in the +z direction by a two-level atom (playing the role of a nonlinear detector) at \( z = z_0 \). In the Coulomb gauge, the interaction between the pulse and the atom is given by [11,14]

\[
H_{\text{int}} = i\hbar \int_0^\infty d\omega g(\omega)e^{i\omega t_0/c}b(\omega)\hat{\sigma}_+ - \text{H.c.},
\]

where \( \hat{a}(\omega) \) is the bosonic operator of the pulse mode with frequency \( \omega \), \( \hat{\sigma}_+ = |e\rangle\langle g| \) is the Pauli operator of the atom with ground state \( |g\rangle \), excited state \( |e\rangle \), and energy splitting \( \omega_{se} \), and the rotating-wave approximation has been used. The amplitude of the atom-field interaction spectrum is given by

\[
g(\omega) = \sqrt{\frac{\omega}{4\pi \varepsilon_0 \hbar c A}}(\vec{e} \cdot \vec{d}_g),
\]

where \( A \) is the effective transverse cross section of the pulse [14,33], \( \vec{d}_g \) the electric-dipole vector of the atom, and we have assumed that the pulse is linearly polarized along the direction denoted by the unit vector \( \vec{e} \). Here, only the pulse modes have been taken into account and the remainder field modes in the environment will be regarded as a bosonic bath of the atom in the following.

The interaction Hamiltonian between the atom and the bath modes is given by

\[
H_{\text{int}} = i\hbar \int d\omega [g(\omega)e^{i\omega t_0/c}b(\omega)\hat{\sigma}_+ - \text{H.c.}].
\]

For a bath mode with wave vector \( \mathbf{k} \) and frequency \( \omega = c|\mathbf{k}| \), the coupling coefficient \( g'(\omega) \) has a form similar to that of \( g(\omega) \) in Eq. (2). It should be pointed out that the prime of \( \int d\omega \) means that the integral over \( \omega \) includes the summation over different polarization and propagating directions of the bath modes with frequency \( \omega \) [14], but excludes the pulse modes which have already been taken into account in Eq. (1).

In the case of a SPFS pulse, the time evolution of the whole system can be solved exactly for some special interaction spectra. The initial state of the total system is assumed to be \( |\psi(t_0)\rangle = |g\rangle|1_a\rangle|0_b\rangle \), where the atom is in the ground state \( |g\rangle \), all the bath modes are in the vacuum state \( |0_b\rangle \), and the state of the pulse modes \( |1_a\rangle \) is given by [33]

\[
|1_a\rangle = \int d\omega \xi(\omega)\hat{a}^\dagger(\omega)|0_a\rangle.
\]

The normalization of the wave packet requires

\[
\int d\omega |\xi(\omega)|^2 = 1.
\]

The details about the spectral amplitude \( \xi(\omega) \) for SPFS pulse of different envelope shapes is given in Appendix A. The Hamiltonians (1) and (3) conserve the total excitation number of the whole system, thus the wave function of the total system at time \( t \) can be expanded in the single-excitation subspace as

\[
|\psi(t)\rangle = \left[ \int d\omega A(\omega,t)\hat{a}^\dagger(\omega) \\
+ \int d\omega B(\omega,t)\hat{b}^\dagger(\omega) + C(t)\hat{\sigma}_+ \right]|G\rangle.
\]

Here, \( |G\rangle = |g\rangle|0_a\rangle|0_b\rangle \) is the ground state of the whole system and the time-dependent coefficients \( A(\omega,t), B(\omega,t), \) and \( C(t) \) are determined by the Schrödinger equation with initial conditions \( A(\omega,t_0) = \xi(\omega) \) and \( B(\omega,t_0) = C(t_0) = 0 \).

After eliminating the degrees of freedom of the field, we obtain the equation describing the exact dynamics of \( C(t) \) (please refer to Appendix B 1 for details):

\[
\frac{d}{dt} C(t) = -\int_{t_0}^t G(t-t')C(t')dt'
\]

\[
+ \int g(\omega)\xi(\omega)e^{i\omega t_0/c}e^{-i(\omega\tau_0-t\tau_0)}d\omega,
\]

where we have removed the fast oscillating factor \( \exp(-i\omega_{se}t) \) of the probability amplitude \( C(t) \) and used the initial condition \( A(\omega,t_0) = \xi(\omega) \). The first and second terms on the right-hand side (r.h.s.) of Eq. (7) dominate the decay and simulation behavior of the atom, respectively. Similar non-Markovian input-output theories have also been developed to handle single-photon storing in a cavity [34] and state transfer in a quantum network [35].
All the memory effects on the decay behavior of the atom is contained in the integral kernel [36,37]

\[ G(t) = \int d\omega |g(\omega)|^2 e^{i(\omega - \omega_d)t} + \int d\omega' |g'(\omega')|^2 e^{i(\omega - \omega_d)t}. \]

We first analyze the Markov approximation of previous works. The usual assumption entails that the bandwidth of the interaction spectrum is much larger than the coupling strength. Then the Wigner–Weisskopf approximation [38,39] applies, which is proved to be equivalent to the Markov approximation [36]. By taking \( |g(\omega)|^2 \) and \( |g'(\omega')|^2 \) out of the integral, the kernel \( G(t) \) is reduced to a memory-less one [11,14,40],

\[ G(t - t') = (\gamma_p + \gamma') \delta(t - t'), \]

where \( \gamma_p = 2\pi |g(\omega_d)|^2 \) and \( \gamma' = 2\pi |g'(\omega_d)|^2 \) characterize the decay of the atom back to pulse modes and the decay to bath modes, respectively. Similar arguments can be applied to the second term on the r.h.s in Eq. (7) and \( g(\omega) \) will be taken out of the integral as a constant. Here we point to this flat-spectrum approximation which is the fundamental reason for instantaneous response times of the single atom [11,15]. As shown in Appendix B, this approximation loses its validity for ultrashort (broadband) pulses as well as in the strong-coupling regime \( (\gamma \approx \kappa) \) of cavity QED.

Instead, we consider here the atom to be placed in a microcavity as shown in Fig. 1(a). Usually, this increases the atom-field coupling strength due to the Purcell effect [41–43]. In this case, the atom-field interaction spectrum is modified by the cavity to be of Lorentzian form,

\[ |g_{\text{cav}}(\omega)|^2 = |g(\omega)|^2 + |g'(\omega')|^2 = \frac{\gamma / 2\pi}{[(\omega - \omega_d)/\kappa]^2 + 1}. \]

where the center of the interaction spectrum is assumed to be at \( \omega_d \) for simplicity, the bandwidth \( \kappa \) is determined by the Q factor of the cavity, and \( \gamma = \gamma_p + \gamma' \) (the spontaneous decay rate under the Markov approximation) characterizes the atom-field coupling strength. In the bad-cavity limit, the incident pulse shape will not be changed significantly by the cavity wall. Note here that we normalize the Lorentzian spectrum to compare with the Markov approximation (flat interaction spectrum) in the \( \kappa \rightarrow \infty \) limit. This corresponds to the bad-cavity or weak-coupling limit of our theory.

After a somewhat lengthy calculation, we finally arrive at a simple and intuitive exact solution for \( C(t) \) (the detailed calculation is given in Appendix B 2),

\[
C(t) = s_1 \left[ e^{-p_1(t-t_0)} C(t_0) + e^{-p_1(t-t_0)} \int_{0}^{t-t_0} e^{p_1 t'} dt' \right] \\
+ s_2 \left[ e^{-p_2(t-t_0)} C(t_0) + e^{-p_2(t-t_0)} \int_{0}^{t-t_0} e^{p_2 t'} dt' \right],
\]

where the decay rates \( p_j \) (also the frequency shift for the strong-coupling case) and the ratio coefficients \( s_j \) for the two branches are given in Appendix B. The \( C(t_0) \) terms have been kept to study the spontaneous decay behavior of the atom.

### III. Limits to Single-Photon Transduction by an Atom

Unlike the ideal photodetector as shown in Fig. 1(b), the output signal of a realistic detector always has a rise and fall time. In this section, we study the details of photon transduction by a single two-level atom. In experiments, the most commonly used waveform is a Gaussian wave packet. In Fig. 2, we present the time-dependent excitation probability \( P(t) \) of the atom stimulated by a Gaussian SPFS pulse. Figures 2(a)–2(c) contrast with the results obtained by the Markovian theory (green lines) and our non-Markovian theory (gray lines) for the weak-coupling regime \( \kappa = 10\gamma \).

We make the key observation that, as the input pulse length \( \tau_f \) is decreased from \( \tau_f = 1/10\gamma \) to \( \tau_f = 1/100\gamma \), the excitation probability \( P(t) \) obtained from the Markovian theory has a rise time which directly follows the input pulse. This implies that ultrashort pulses can cause sharp rise times in the single atom with no limit albeit with a low maximum in the excitation probability [see red arrow in Fig. 2(c)]. This is a consequence of the Markovian approximation by replacing \( g(\omega) \) with a constant \( \sqrt{\gamma_p/2\pi} \) in Eq. (11) [11,14,15]. A closer look made possible by our non-Markovian theory shows that the rise time (gray lines) does not reduce as the pulse length is decreased. A clear bound exists on the fastest possible rise time even for a single-atom excitation probability \( P(t) \). This rise time is limited by the atom-field interaction spectrum width \( \kappa \).

In Fig. 2(d), we study the influence of the coupling strength on the atom excitation probability \( P(t) \). In the case of weak coupling \( \kappa = 10\gamma \), just as expected, there is no significant difference in the value of the probability \( P(t) \) with (dashed green line) or without (solid gray line) the Markovian approximation in the weak-coupling case, while a significant variation occurs in the strong-coupling case (the dotted red line with \( \kappa = \gamma \)). The strong coupling enhances the excitation probability of the atom \( P(t) \) when \( \tau_f \sim 1/\gamma \) for the Gaussian SPFS pulse.

### A. Concept of quantum jitter time for a single atom

We elucidate here the concept of a quantum jitter time for a single atom. For the deterministic output signal of a classical system, e.g., the voltage signal of an RC circuit as shown in Fig. 1(c), the characteristic rise time and fall time do not imply a timing jitter unless noise is added. In the case of a quantum output as shown in Fig. 1(d), the probabilistic nature of the waveform implies that there exists fundamental uncertainty in time stamping an event such as photon transduction. For the sake of discussion, we analyze the probability of excitation of the single atom as an output waveform. Evidently, this output signal has a finite rise time for an incident pulse with finite length. Under the previously used Markovian approximation, we immediately notice that, as the pulse length gets shorter, the rise time of the excitation probability is infinitesimal. This implies, in principle, that time stamping of transduction is deterministic for a single photon by a single atom. However, our non-Markovian theory predicts that, even for a 5-function input Fock-state pulse, the rise time is finite and limited by the atom-field interaction spectrum bandwidth. Note that the probability of excitation tends to zero for this narrow-band atomic detector but the rising rate (inverse of the rise time)
is finite, not infinite. We emphasize that the finite rise time to the output waveform immediately implies that there exists a quantum jitter in the absorption event. Thus, even if the atom were completely characterized, the photon-absorption event can occur anywhere within this finite rise time and fall time in subsequent experiments.

In most systems, the weak-coupling condition $\gamma \ll \kappa$ for the spontaneous decay process is well satisfied. In this case, the Wigner–Weisskopf approximation is applicable to the first term on the r.h.s. of Eq. (7) by replacing the memory kernel $G(t - t')$ with $\gamma\delta(t - t')$. But the same approximation cannot be made on the second term, especially when the width of the pulse spectrum $1/\tau_f$ is of the same order or even larger than the interaction spectrum width $\kappa$. Then, the solution for $C(t)$ is given by

$$C(t) = e^{-\frac{t}{\tau_f}} \int_0^{t/\tau_f} dt' e^{\frac{t'}{\tau_f}} \int_0^{\infty} d\omega \xi(\omega) e^{\frac{\omega t}{\tau_f} - i(\omega - \omega') t'}.$$

(12)

To get the analytic limit on photon transduction time, we take the Lorentzian interaction spectrum (B6) as an illustration and study a special case, where the length of the pulse is infinitely short ($\delta$ pulse). Frankly speaking, incident broadband pulses can be reshaped by a narrowband cavity. However, our focus here is the rise time of the atom caused by the stimulated absorption. This fundamental limit in the rise time is independent of the pulse shape and is a property of the atom-cavity interaction spectrum bandwidth. Furthermore, we note that non-Markovian dynamics can occur even in the weak-coupling limit since the broadband nature of the pulse is the fundamental origin of the non-Markovian dynamics.

In the case of weak coupling $\gamma \ll \kappa$ using a $\delta$ pulse with a constant spectrum amplitude $\xi(\omega) = \xi_0$, the solution of $C(t)$ reduces to the much simpler form

$$C(t) = \xi_0 \sqrt{2}\gamma \kappa e^{-\gamma(t - t_0)/2} C_R(t),$$

(13)

where the fall time of $C(t)$ is determined by the spontaneous decay rate $\gamma$ and the rise time is determined by the monotonically increasing function

$$C_R = \int_0^{t_0} \Theta(t' - z_0/c) \kappa e^{-\kappa(t' - z_0/c)} e^{\gamma t'/2} dt',$$

(14)

with the Heaviside step function $\Theta(t)$. Note that, in the Markovian limit $\kappa \rightarrow \infty$, the function $e^{\kappa[|t' - z_0/c|]} \rightarrow \delta(t' - z_0/c)$, then the rising edge of $C(t)$ disappears (see solid-light-blue line in Fig. 3) and $C(t)$ decays instantaneously after the arrival of the pulse (zero rise time), i.e., $C(t) = \xi_0 \sqrt{\gamma} \kappa e^{-\gamma(t - t_0 - z_0/c)/2}/2$. However, for a finite atom-field interaction spectrum $\kappa$, the width of the rising window of $C_R(t)$ is determined by the width of its rising speed, i.e., its time derivative

$$\frac{d}{dt} C_R(t) = \Theta(t) \kappa e^{-\kappa t + \gamma t/2},$$

(15)

where we have set $z_0 = 0$ for simplicity. In the weak-coupling limit $\gamma \ll \kappa$, the width of the rising speed $dC_R(t)/dt$ is approximated as $1/\kappa$ (see the dotted-red line Fig. 3). Thus the
FIG. 2. Excitation probability $P(t)$ of the atom stimulated by single-photon Fock-state pulse. Here, we take the Markovian spontaneous decay rate of the atom as the unit $γ = 1$. (a)–(c) Comparison of $P(t)$ obtained by Markovian theory (dashed-green lines) and non-Markovian theory (solid-gray lines) for different pulse lengths. Here, the width of the interaction spectrum $κ$ is taken as $κ = 10γ$ for non-Markovian theory and $κ → ∞$ for Markovian theory and the vertical dashed lines show the position of the maximum of the non-Markovian excitation probability $P(t)$. The pulse lengths in panels (a)–(c) are taken as $τ_f = 1/10γ$, $τ_f = 1/20γ$, and $τ_f = 1/100γ$, respectively. As indicated by the red arrow in panel (c), the rise time of $P(t)$ under the Markovian approximation will go to zero when the pulse length $τ_f → 0$. The solid-gray lines of the non-Markov clearly show there exists a finite rise time to the excitation probability of the single atom. (d) Comparison between the weak-coupling and strong-coupling regime of cavity QED. Here, the pulse length is set as $τ_f = 1/γ$. The dashed green line is obtained by the Markovian theory. The solid gray line and dotted red line correspond to the weak-coupling case ($κ = 10γ$) and the strong-coupling case ($κ = γ$), respectively. High excitation probability $P(t) > 0.96$ (see the red-circled upper limit 1) is obtained in the strong-coupling regime for the Gaussian pulse.

width of the rising edge of $C(t)$ as shown by the dashed-blue line in Fig. 3 as well as the the rising edge of the excitation probability $P(t)$ has a lower limit $∼ 1/κ$.

We define the excitation probability density of the atom by normalizing $P(t)$,

$$P(t) = \frac{P(t)}{\int P(t)dt}.$$  

The transduction time of a photon by an atom is characterized by the width of envelope of the excitation probability density $P(t)$, which equals the sum of the widths of the rising and falling edges of $P(t)$. For the weak-coupling case, the fastest rise time and fall time of the atomic probability of excitation is given by

$$Δ = 1/κ + 1/γ.$$  

We note that the first time constant corresponds to a finite rise time (transduction) and the second constant corresponds to a fall time (spontaneous decay of the atom into field modes and bath modes). For a realistic detector, the decay after the transduction is irreversible and will occur into the large set of amplifier modes. The fall time can also be directly controlled via density-of-states engineering. But the rise time is set by the bandwidth of detector-field coupling, which cannot be eliminated. We can now analyze the consequence of the above equation for a solid-state system. Note that the transduction event of light in a solid is governed by the electron-electron interaction which sets an upper limit (tens of femtoseconds for normal metals and semiconductors) for the rate of absorption [44,45]. This will inevitably cause a jitter at least of the order of electron-electron interaction time.

IV. SPECTRAL MATCHING IN PHOTON TRANSDUCTION

For a single-photon detector, fundamental characteristics such as quantum efficiency are considered independent of the input field. This is evident in approaches such as detector tomography [46], which are agnostic to the detector modes. Our concept of quantum timing jitter and spectral matching can be incorporated in the formal theory of positive-operator valued measure (POVM) [47,48]. As shown in the previous part, the excitation probability of detector modes and its time evolution in the transduction event depends on the spatiotemporal input Fock state and field-detector interaction spectrum. Thus it is probable that the spectral, spatial, and temporal response characteristics of a single-photon detector is sensitive to the chosen single-photon waveform. To explore this idea, we consider the role of the spectral overlap between the SPFS pulse and the atom-field interaction spectrum. From Eqs. (7) and (11), we find that the temporal pattern of the rising edge of $C(t)$ is determined by the overlap between the pulse spectrum $E(ω)$ and the atom-field interaction spectrum $g(ω).$ We show that the maximum of excitation probability $P(t)$ can be optimized by matching these two spectra. Note that we do not assume a flat
or constant interaction spectrum as in previous works and our theory also works in the strong-coupling regime ($|g| > \kappa$).

The value of the excitation probability $P(t)$ is determined by the overlap integral of interaction spectrum $g(\omega)$ and pulse spectrum $\xi(\omega)$, as can be seen from Eq. (11). In the frequency domain, the width of the pulse spectrum $|\xi(\omega)|^2$ is given by $1/\tau_f$. Thus, for a given interaction spectrum, the maximum excitation probability $P(t)$ can be optimized by changing the pulse length. In Fig. 4, we give the results of numerical optimization of $P(t)$. The three columns represent SPFS pulses with envelopes of Gaussian, decaying exponential, and rising exponential, respectively. In Figs. 4(a)–4(e), different lines represent different pulse lengths and different coupling strengths (different interaction spectrum width $\kappa$). A larger maximum of $P(t)$ can be obtained when the incident pulse has an optimized length $\tau_f \approx 1/\gamma$. For an optimized spectrally matched pulse $\tau_f = 1/\gamma$, the stronger coupling strength will enhance the maximum excitation probability $P(t)$ for Gaussian [Fig. 4(a)] and decaying exponential pulses [Fig. 4(b)]. However, this depresses $P(t)$ for rising exponential pulses [Fig. 4(c)]. It should be pointed out that the maximum of $P(t)$ for a Gaussian pulse obtained from our non-Markovian theory $\sim 0.96$ is larger than the Markovian one $\sim 0.8$ obtained in previous studies [11,13].

In Figs. 4(d)–4(f), we plot the maximum of $P(t)$ as functions of pulse length $\tau_f$ and interaction spectrum width $\kappa$. We find that the global maximum of $P(t)$ is always located at $\tau_f \approx 1/\gamma$. To investigate the influence of the atom-field coupling strength on the global maximum of $P(t)$, we reexpress the probability amplitude $C(t)$ in Eq. (11) as $C(t) = C_1(t) + C_2(t)$ with

$$C_j(t) = s_j \int d\omega \frac{g(\omega + \omega_d)p_j}{p_j - i\omega} \xi(\omega + \omega_d)e^{-i\omega t}. \quad (18)$$

Here, the integral variable $\omega$ is replaced with $\omega + \omega_d$, the position of the atom is set as $z_0 = 0$ for simplicity, and the lower limit of the integral over $t$ has been extended to $-\infty$ without loss of generality. In the weak-coupling case $\gamma \ll \kappa$, one has $s_1 \approx 1$, $p_1 \approx \gamma$ and $s_2 \approx 0$, $p_2 \approx \kappa$. Almost, only $C_1(t)$ has a contribution to $C(t)$. In the strong-coupling region $\kappa \approx \gamma$, the decay rate of both $C_1(t)$ and $C_2(t)$ is given by $\text{Re}[p_j] = \kappa \approx \gamma$. The maximum of the probability amplitude $\kappa^* \frac{1}{\gamma^*}$ is determined by the overlap of the interaction spectrum $g(\omega)$, the pulse spectrum $\xi(\omega)$, and a factor $\sim 1/(\gamma - i\omega)$. This is why the global maximum of $P(t)$ is located at $\tau_f \approx 1/\gamma$.

V. LINEAR PHOTODETECTOR VS NONLINEAR DETECTOR

In this section, we shed light on the difference between a linear photodetector—a harmonic oscillator—and a nonlinear one—a single two-level atom. The Fock-state and coherent-state pulses have different statistical properties causing fundamental differences in excitation probabilities [9]. The SPFS pulse has fixed photon number $\bar{n} = 1$ and zero variance $\Delta n = 0$. However, for a single-photon coherent-state (SPCS) pulse with mean photon number $\bar{n} = 1$, the corresponding variance is given by $\Delta n = \sqrt{\bar{n}}$. As we show below, the harmonic-oscillator detector cannot distinguish between the SPFS and SPCS pulses. Its output is linearly proportional to the strength of the incident pulse. But, for a single-atom detector, the output waveforms of SPFS and SPCS pulses are very different.

The collective modes in a detector can be well modeled as harmonic oscillators. Here, we just consider one of the harmonic modes (described by the bosonic operators $\hat{d}$ and $\hat{d}^\dagger$), which is resonant with the center frequency of the incident pulse $\omega_0$. The motion equation of this linear photodetector is given in Appendix B3. The output waveform of this linear

APPENDIX A: WAVE FUNCTION OF QUANTIZED PULSE

The theory of quantization of the continuous-mode field is given by Ref. [33]. In the Coulomb gauge, the positive-frequency part of the electric-field operator of the pulse can be expanded as [9,33]

$$\hat{E}(z) = i \int_{0}^{\infty} d\omega \sqrt{\frac{\hbar \omega}{4\pi \varepsilon_0 c A}} \hat{a}(\omega) e^{i\omega z/c}, \quad (A1)$$

where the constant $c$ is the speed of the light in vacuum, $\varepsilon_0$ is the permittivity of the vacuum, $A$ is the effective cross section of the pulse, and the field operators $\hat{a}(\omega)$ follow the bosonic commutation relation

$$[\hat{a}(\omega), \hat{a}^\dagger(\omega')] = \delta(\omega - \omega'). \quad (A2)$$

By taking the electric-dipole approximation, one can easily obtain the interaction Hamiltonians between the atom and the continuous-mode field in Eqs. (1) and (3).

The wave function of a single-photon Fock-state pulse with a spectral amplitude $\xi(\omega)$ is given in Eq. (4). The Fourier transform of $\xi(\omega)$ gives the wave-packet amplitude in the time-space domain:

$$\xi(t, z) = \frac{1}{\sqrt{2\pi}} \int d\omega \xi(\omega) e^{-i\omega(t-z/c)}. \quad (A3)$$

In this paper, the following four types of pulse are used:

(i) Gaussian pulse with wave-packet amplitude in the time-space domain,

$$\xi(t, z) = \left(\frac{1}{2\pi \tau_f^2}\right)^{1/4} \exp \left[-\frac{(t-z/c)^2}{4\tau_f^2} - i \omega_0 \left(t\tau_f - \frac{z}{c}\right)\right], \quad (A4)$$

where $\tau_f$ is the pulse length and $\omega_0$ is the central frequency, which is assumed to be resonant with the atom, i.e., $\omega_0 = \omega_0$. The corresponding spectral amplitude in the frequency domain reads

$$\xi(\omega) = \left(2\pi \tau_f^2/\pi\right)^{1/4} \exp \left[-\tau_f^2(\omega - \omega_0)^2\right]. \quad (A5)$$
(ii) Decaying exponential pulse with wave packet,
\[ \xi(t,z) = \begin{cases} 0, & t < z/c \\ \frac{1}{\sqrt{\tau_f}} e^{-i(1+2i\omega t_f)(t-z/c)}, & t \geq z/c, \end{cases} \] (A6)
and the corresponding spectral,
\[ \xi(\omega) = \sqrt{\frac{2\tau_f}{\pi}} \frac{1}{1 - 2i(\omega - \omega_0)\tau_f}. \] (A7)

(iii) Rising exponential pulse with wave packet,
\[ \xi(t,z) = \begin{cases} \frac{1}{\sqrt{\tau_f}} e^{+i(1-2i\omega t_f)(t-z/c)} & t \leq z/c, \\ 0, & t > z/c, \end{cases} \] (A8)
and the corresponding spectral,
\[ \xi(\omega) = \sqrt{\frac{2\tau_f}{\pi}} \frac{1}{1 + 2i(\omega - \omega_0)\tau_f}. \] (A9)

(iv) Infinitely short \( \delta \) pulse, e.g., the pulse length of the Gaussian type in Eq. (A4) goes to zero. The corresponding spectral can be replaced with a constant \( \xi(\omega) = \tilde{\xi}_0 \propto \tau_f \).

In addition, the wave function of a single-photon coherent-state pulse is given by
\[ |\psi_f\rangle = \prod_\omega |\xi(\omega)\rangle, \] (A10)
where \( |\xi(\omega)\rangle \) is the eigenstate (coherent state) of the field operator \( \hat{a}(\omega)|\xi(\omega)\rangle = \xi(\omega)|\xi(\omega)\rangle \). The amplitude \( \xi(\omega) \) satisfies \( \int d\omega |\xi(\omega)|^2 = \tilde{n}_f \), with the mean photon number in each pulse \( \tilde{n}_f \).

APPENDIX B: EXACT DYNAMICS OF PHOTODETECTOR

In this Appendix, we give some detailed calculations of the dynamics of the atom interacting with the continuous-mode field. For the single-photon pulse with visible wavelength, the thermal excitation can be neglected and the wave function of the total system is expanded in the single-excitation subspace as in Eq. (6).

1. Motion equations

The equations of the coefficients \( A(\omega,t) \), \( B(\omega,t) \), and \( C(t) \) in Eq. (6) are given by the Schrödinger equation,
\[
\frac{d}{dt} A(\omega,t) = -g^*(\omega)e^{-i(\omega - \omega_0)t} C(t) e^{i(\omega - \omega_0)(t-t_0)},
\] (B1)
\[
\frac{d}{dt} B(\omega,t) = -g^*(\omega)e^{i(\omega + \omega_0)t} C(t) e^{i(\omega + \omega_0)(t-t_0)},
\] (B2)
\[
\frac{d}{dt} C(t) = \int d\omega g(\omega) e^{i(\omega + \omega_0)t} A(\omega,t) e^{-i(\omega - \omega_0)(t-t_0)}
+ \int d\omega g^*(\omega) e^{i(\omega + \omega_0)t} B(\omega,t) e^{-i(\omega - \omega_0)(t-t_0)}. \] (B3)

Here, these equations are obtained in the interaction picture, thus the fast oscillating factors in \( A \), \( B \), and \( C \) have been removed. The formal solutions of \( A \) and \( B \) read
\[
A(\omega,t) = \xi(\omega) - \int_{t_0}^t dt' g^*(\omega)e^{-i(\omega - \omega_0)(t-t_0)} e^{i(\omega - \omega_0)(t-t_0)}, \] (B4)
\[
B(\omega,t) = \int_{t_0}^t dt' g^*(\omega)e^{i(\omega + \omega_0)(t-t_0)} e^{-i(\omega + \omega_0)(t-t_0)}, \] (B5)
where we have used the initial conditions \( A(\omega,t_0) = \xi(\omega) \) and \( B(\omega,t_0) = 0 \). Substituting these formal solutions into Eq. (B3), the effective equation for \( C(t) \) given in Eq. (7) is obtained.

The total atom-field interaction spectrum is divided into \( |g_{tot}(\omega)|^2 = |g(\omega)|^2 + |g'(\omega)|^2 \), representing the coupling of the atom to the pulse modes and bath modes, respectively. Under the Wigner–Weisskopf approximation, these two parts contribute two decay rates of \( C(t) \): \( \gamma_p = 2\pi |g(\omega_d)|^2 \) and \( \gamma' = 2\pi |g'(\omega_d)|^2 \).

In the following, we focus on the solution of \( C(t) \) in the case of a Lorentzian interaction spectrum in Eq. (10). The coupling amplitude \( g(\omega) \) is chosen as
\[ g(\omega) = \sqrt{\frac{\gamma_p}{2\pi(\omega - \omega_0)/\kappa + i}}. \] (B6)
For the Lorentzian interaction spectrum, the corresponding memory kernel \( G(t-t') \) reads
\[ G(t) = \int d\omega |g_{tot}(\omega)|^2 e^{-i(\omega - \omega_0)t} = \frac{\gamma \kappa}{2}\gamma \kappa e^{-\kappa|t|}, \] (B7)
where \( \gamma = \gamma_p + \gamma' \) and we have extended the lower limit of \( \omega \) in the integral (B7) to \(-\infty\), since \( \kappa \ll \omega_d \). To get the results for the strong atom-field coupling regime in the last two sections of the paper, the interaction spectrum is taken to be of the Lorentzian form. This limitation can be removed in the weak-coupling case and the excitation probability \( P(t) \) can be easily obtained numerically via Eq. (12) for arbitrary interaction spectrum \( |g(\omega)|^2 \).

2. Exact solution for Lorentzian spectrum

To get the exact solution of \( C(t) \), we take the following Laplace transform:
\[ f[p] = \mathcal{L}[f(t)] = \int_0^{\infty} e^{-pt} f(t) dt, \] (B8)
\[ f(t) = \mathcal{L}^{-1}[f[p]] = \int_{-i\infty}^{i\infty} e^{pt} f[p] dp, \] (B9)
of Eq. (7). Then, we have
\[ C[p] = F[p]\left[ C(t_0) + \int d\omega \frac{g(\omega)}{p + i(\omega - \omega_0)} \xi(\omega) e^{i(\omega - \omega_0)t_0} \right], \] (B10)
where the initial value \( C(t_0) \) is kept to study the spontaneous decay behavior of the atom and the singularities of \( F[p] = \left[ p + i(\omega - \omega_0) \right]^{-1} \) will be used to carry out the inverse Laplace transform.

When \( \kappa \neq 2\gamma \), we can split \( F[p] \) into
\[ F[p] = \frac{s_1}{p + p_1} + \frac{s_2}{p + p_2}, \] (B11)
where $p_j = [\kappa + (-1)^j \sqrt{\kappa^2 - 2\gamma^2}] / 2$ are the poles and $s_j = [1 - (-1)^j \sqrt{1 - 2\gamma^2/\kappa}] / 2$ are the corresponding expanding coefficients with $j = 1, 2$. The real and imaginary parts of $p_j$ ($j = 1, 2$) correspond to the decay rate and the Lamb shift, respectively. The inverse Laplace transform of $C[p]$ gives the solution of $C(t)$ in Eq. (11).

For the special case $\kappa = 2\gamma$, we have $p_1 = p_2 = \gamma$ and

$$F[p] = \frac{1}{p + \gamma} + \frac{\gamma}{(p + \gamma)^2}.$$  \hspace{1cm} (B12)

The inverse Laplace transform of $C[p]$ gives

$$C(t) = \left[ e^{-\gamma(t-t_0)} C(t_0) + \int_{t_0}^{t-t_0} dt' e^{-\gamma(t-t')} \times \int d\omega \xi(\omega) e^{i\omega t_0/c} e^{-i\omega t} \right]$$

$$+ \left\{ \gamma(t-t_0) - \gamma e^{-\gamma(t-t_0)} C(t_0) + \int_{t_0}^{t-t_0} dt' \gamma(t-t') e^{-\gamma(t-t')} \times \int d\omega \xi(\omega) e^{i\omega t_0/c} e^{-\omega t} \right\} dt'.$$  \hspace{1cm} (B13)

In the weak-coupling case $\gamma \ll \kappa$, we can expand the coefficients $p_j$ and $s_j$ to the first order of $\gamma/\kappa$ to obtain $p_1 \approx \gamma / 2$, $p_2 \approx \kappa$, $s_1 \approx 1 + \gamma / 2\kappa$, and $s_2 \approx -\gamma / 2\kappa$. The second branch has a much larger decay rate $p_2 \gg p_1$ and much smaller weight factor $|s_2| < |s_1|$. In this case, for $t > 1 / \kappa$, we can neglect the contribution from the second branch. This is the reason why a pure exponential spontaneous decay is observed in most experiments.

To reveal the decay behavior of the atom, we study the spontaneous decay process of the atom with initial conditions $C(t_0) = 1$ and $A(\omega, t_0) = B(\omega, t_0) = 0$. For $\kappa \neq 2\gamma$, the probability of the atom staying in the excited state at time $t$ is given by

$$P(t) = |C(t)|^2 = [s_1 e^{-\gamma(t-t_0)} + s_2 e^{-\gamma(t-t_0)}]^2.$$  \hspace{1cm} (B14)

Usually, the probability $P(t)$ will not be a simple exponential decay. This nonexponential decay has already been found by Imamoğlu in 1994 [51]. Only in the weak-coupling case $\gamma \ll \kappa$ does the probability approximately decay exponentially as $P(t) \approx \exp[-\gamma(t-t_0)]$. As shown in Fig. 6, the probabilities of the atom in the excited state $P(t)$ from the weak-coupling regime (dash-dotted black line) to the strong-coupling regime (solid-blue line) are displayed.

3. Quantum Langevin equation for a linear detector

In the previous part, the single-photon transduction by a nonlinear detector (a two-level atom) was studied. A similar method can be applied to a linear-detector case—a harmonic oscillator. If the atom is replaced by a harmonic oscillator with frequency $\omega_0$, we can easily obtain the quantum Langevin equation for the annihilation operator $\hat{d}$ of the the oscillator [40],

$$\frac{d}{dt} \hat{d}(t) = - \int_{t_0}^{t} G(t-t') \hat{d}(t') dt' + \hat{a}_m(t) + \hat{b}_m(t).$$  \hspace{1cm} (B15)

where the memory kernel $G(t)$ is the same as that in Eq. (8) and the operators

$$\hat{a}_m(t) = \int d\omega \hat{a}(\omega, t_0) e^{i\omega_0 t_0/c} e^{-i(\omega_0 - \omega)t},$$  \hspace{1cm} (B16)

$$\hat{b}_m(t) = \int d\omega \hat{b}(\omega, t_0) e^{-i\kappa z_0} e^{-i(\omega_0 - \omega)t},$$  \hspace{1cm} (B17)

represent the input from the pulse modes and bath modes, respectively. As a generalization of the traditional input-output theory [40], the signal and noise field modes are handled separately. Different from the noise operator $\hat{b}_m(t)$, the input signal operator $\hat{a}_m(t)$, which is determined by the incident pulse, cannot be simply treated as a white-noise operator.

Finally, it should be point out that, to get a larger excitation probability $P(t)$ and to compare the results obtained by our non-Markovian theory with the previous Markovian theories [11,13], we let $\gamma_p = \gamma$ during the calculation. Thus, all results obtained in this paper should be modified by a factor $\gamma_p / \gamma$. This factor denotes the proportion of the pulse modes in the total field modes. For three-dimensional free space, we assume that the polarization of the pulse is parallel to the direction of the electric dipole. In this case, the factor reads $\gamma_p / \gamma = 3/8\pi$.

For a 1D wave guide, if the cross section is small enough, the modes with wave vector in the $xy$ plane ($\hat{k} \cdot \hat{z} = 0$) can be neglected. In this case, the factor is $\gamma_p / \gamma = 1/2$. Usually, to realize an efficient coupling of photons to a single atom in an experiment, the incident light pulse is focused onto the atom by an antenna [52,53] or a parabolic mirror [54]. The factor $\gamma_p / \gamma$ can reach near 100% [55].
